## INTRODUCTION

Landimgs of mackerel by 1 mish vessels have increased dramatically in recent years. The total catch in 1902 amounted to 110 ooo tonnes which was valued at about 8.5 million pounds, compared with only 8 goo tonnes, values at o. z , million pounds in 1974. The mejor cause of the increase has been the introduction of six large trablers into the fleet around 1000 as a result of which the total catch jumped from 24000 tomes in 1979 to 80000 tommes in 1980 . The majn landings into Irish ports are made at killybegs and Fathmullang while smaller landimge are made joto Castletownbere and Galway bimce 1 gag considerable quantities have al wo been landed into western seottish ports. Most of the catches are taken off the wewt and northwest
 over a mide area extemding from west of the bhetimmelanda down to Cornwall.

Qver $95 \%$ of the total cateh $i=$ exportedy mainly in the form of whole frozen fish. These fish are frozen ejther ashore or on freezer vessels and are then trameported mainly to Niberia and other African countries including Ivory Coact and Egypt.

It has become obvious that over the last few years exporters are becoming increasingly conscious of the necessity to provide eertain sperification about their products for various countries. These specjfications concern the length, weight of imdividual fishy the presence or absence of food in the gut, the degree of infestation with parasitic worms and the fat content of the flesh. Exporters in general. Eexem to require more information about the type of product with winct they are dealing than in the more distant past. Considerable information about come of these topicsy eng. Iemgth, weight, fat content anc pianasitic infestation is obtained in the course of routime sempling for stoct assessment purposes. The purpose of this paper therefore is to present this information in a form which may prove umeful to exporters in anticipating the type of mackerel which may become avajlable and in deecribing the type of fish available in a particular landing.

## Length/Age

The total length is measured from the snout to the tip of the tail. Mackerel are consjuered to be a fast growing fish - eng. mackerel. which have been spawned in spring or early summer may reath about zocm by the end of their first yearn These smaju fish were heavily exploited in the fishery off Cornwall berome a ban on fishing was introduced in the area. In recent years, 1984 and 1905 , Emall mackerel have been 1 owated northwest of Domegal and it is now thought that there has been a change in the nursery area for juvenile fish. Most mackerel become Eexually mature after two or three yeare and may Iive up to 1 wor 16 years of age - by which time they may be over 45 cm 1ong. In general there is a considerable variation jn the lengths of mackerel taten by fr bh boats depencimg on the area and season of the fisheries. Shoals of large mackerel are taken durimg the months Detober to February as they migrate to and from the overwintering grounds. Durimg the summer the large mackerel migrate far to the north so that the catches taken around our coasts consist majnly of gmall fish. Tn Fig. 1 the $]$ Ength distributione of eatches taken during February, May, July and November 1984 are shown and demonstrate Elearly the seasonal differences of the eatches. These seasomal variations in length are typical of the pattern over the last few years.

## Weiqht and numbers of fish per kilogramme

The aver age weight of individual fish increases throughout the life span - Exc. fish at the end of: their firct. year (1 year old) may be about 45 g , while a 2 year old fish may average about fyogn A fish about 15 or 16 years of age may weigh 1500 g , while octamamal. specimenc attain over 20o0g. Consideratele variation occurs in the weight of an individual fish throughout the year. In general fish are at their thimnest in march and mpril after winter but increase in wejght as Epewning appromches in spring and eerly summer. Atter spamming the fish feed voraciously, put on weight rapidiy and are at their heaviewt during Oetoher to December. Gmad mackerel which grow much faster than the 3 arger fish may increase their weight by over zs $\%$ and lerge fish by $17 \%$ from the $15 t$ to the $4 t h$ querter.

The relationship between 1 engith and weight of fish landed in to the Donegel ports bewed on the years $190 \mathrm{~s}-1984$ are shown in the following text table. The relationships are shown for the $1 s t, 2 n d$ and 4 th quarters of the year. The average weights of fisti are smallest. in the 2nd quarter (i.e. April-Jume) because this period corresponds with the immediatee post Epewning period.

Average weight (gm) per length group (cm) and equivalent numbers per kilogramme per quarter

| Length Eroup (cm) | Q 1 | 02 | 03 |
| :---: | :---: | :---: | :---: |
| 25-26 | 107 | 133 | - |
|  | (9,3) | (7.5) | - |

|  | (2.4) | (2.4) | (2.2) |
| 39-40 | 523 | 474 | 584 |
|  | (1.7) | (2.1) | (1.7) |
| 41-42 | 614 | 570 | 672 |
|  | (1.6) | (1.8) | (1.4) |
| 43-44 | 716 | 663 | 776 |
|  | (1.4) | (1.5) | (1.2) |
| 45-46 | 806 | 678 | 920 |
|  | (1.2) | (1.5) | (1.1) |

## Fat content

Mackerel store fat throughout their bodies - mainly in the muscles and in the liver. In common with other fish the fat content varies considerably throughout the year. In addition there are considerable veriations between individual fish depending on their sizes and the degree of ripeness of the reproductive organs. Mackerel have a prolonged spawning period, unlike herring, and the main spawning lasts from March to June. Since this period follows the winter when food is ecarce and also because fat is used to produce milt and eggs, the fat content of the flesh is at a minimum duirmg gpring and early summer. However, as food becomes available in early summer the fat content rapidly rises and reaches a maximum by October and November. Finally, it graduelly decreases during the winter monthe.

Fig. 1 .Typical length distributions of catches, showing variations for selected months.

The results of all the semple examined are shown in fig. 2 for small, medjum and large fish.

These are based on samples of fillets examinem simes 19 B . Ascan be seen there is a comsiderable variation between the fat content of the small and large fjeh particularly during the periods when the fat is at a maximum level i.e. during the main autumn and winter fisheries. Durjog this period the average difference between 1 arge arid smell fish is about $10 \%$ for this reason the average fat content of a sample may not be meaningful unless information on the relentive quantities of fish in mem size cetegory is provided.

The fat content therefore should always be coupled with some information about the relative proportions of each size rategory or if possible geparate fat: contents should be given for each category.

The mathod used in analysing fat content is one developed by Foss Electric, Denmart and is based on the extraction of fat from minced fillets。

## Infestation rates of Anisakis sp larvae in mackerel

Mackerel, in oommon with most other types of fish, are hosts to a number of different parasitwes. The most important perasites from a commeridal point of view are the larval stages of the nematode worm Anjsekis. The adult stages of these parasjtes are found in warm-blooded animels - eq. wheles, dolphins and porpoises which feed on fish. Anisetis is very resjetent to extremes of temperature and can survive various procestes including marinatingn All larval. Amisatis can be killed by subjecting individual fish to temperaturec of - -17 C for 24 hours. On a commercial wadey freezing of commercial block (45 kg) at -30 C for 16 hours followed by storage at -12 C killed nearly all larvae within 24 hours and any survivore within 1. week (GuEtofon 1 g巨s) " The presemce of live Anisatis may ocmur in fish which have not been properly cooked and may therefore tabse problems in humans. ln live figh the 1 arvae are foumd anywhere on the viscere but are mostly loceted in the mesenteries and the fatty deposits mear the rectum. When the mackerel are dead the parasites tend to burrow into the muscles of the fillets and encyst there if they cannot escape. The number of 1 arvae therefore found in the muscles will increase as the time increases between capture and freezimg. It is important therefore that fish should be frozen to tine correct temperature as soon as possible after capture.

Mackerel were examined to study the infestation rate of 1 arval nematodes between November 1984 and March 198 Gy duming the mein mackerel finmery off the Nomthwest coast. Fish examined up to mid-December had been previously graded and frozen and the results can be used as an indication of the extent of infestation of frozen fish. Fish examined after this were fresh and ungraded and whe results are probably more prepresertative of the normal population.

In all cases fish were ppemed and the davae were removed and count:ed, after a coreful Eearch of the body cavity and various organs. No attempt was made to Jofate any parasites which had migmatect into the muscles. However, in the initial stages of the investigation some studies in this respect, using pepsin and hydrochloric acid digestion methods, indicated that some paragites had already lodged themselves in the fillets and were mot visible to the naked even The results, therfore only give an indication of the total number of parasites present in each fish.

A totel of 6we frozen graded mackerel and 456 fresh ungraded madkrel were examined. Fish ere also measured (total length) because it has been Ehown that in other species the number of larvae increases as the fish gets older and bigger.

## Results

The results of al. samples, showing the number of fish examined, the percentage of fish inferted with gnisatcis the average number of Anjeakis present per fish and per infected fish and them maximum number. found per fish are ghown in the following tablen

| Date | Location | Number Examined | \% infected | Average/ fish | Average/ infected fish | Maxima |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| ov(frozen) + | N.W. Scotiland | 201 | 65 | 6.4 | 9.5 | - |
| ov/Dec(")+ | " | 194 | 62 | 6.9 | 12.4 | - |

| 6 Feb | Tory Island | 84 | 93 | 6.8 | 7.3 | 77 |
| 26 Feb | Slyne Head | 107 | 80 | 5.3 | . 6.7 | 35 |

+Does not include some large fish.

Fig. 1 .Typical length distributions of catches, showing variations for selected months.

In gemeral the majority of fish ( $970 \%$ ) have some level of infestation. While the level of infestatiom may vary considerably im inctividual fish (O-10s larvae per fish) the average number per fish from different samplea only ranged from 3.7 to 12.4.

The average number or Amisatis fish (non frozen) at differfent lemgth groups showed no apparent increase as fish became larger. This is in contrast to the case in herring where, however, it has beemshown that the average number of parasites present per fish increases consistently as fish get older and larger.

Averame mumers per fish

Despite an extensive searm of available literature no references could be foumd to the level= of intestation of anisebis in mackerel from other areas. It whuld appear, however, that even though most fish do contain these paramites the intestation retep per indivicual fish may be low and if fich are quickly and properly frozen after capture no dangers to human health should arise.
