Marine Institute, Fisheries Research Centre, Abbotstown, Dublin 15.

#### Abstract

Stocks of cod, whiting, plaice and sole in ICES Divisions VIIb,c and VIIj,k are an important part of the Irish fishing resource yet, until 1993, were not subject to any assessment. Landings of these stocks in 1996 were valued at $£ 8.6$ million, representing $17 \%$ of the overall value of all Irish landings of demersal species. In 1993, the Fisheries Research Centre initiated a stock monitoring programme with the aim of providing adequate data to enable an assessment of these stocks. This paper presents the results of growth, catch curve and yield per recruit analyses from the monitoring programme conducted between 1993 and 1996. Preliminary results show that all of these stocks but sole in VIIb,c are over-exploited. TAC levels (based on reported catches in previous years) may be inappropriate for the current stock sizes. It is also important to compare biological characteristics between ICES Divisions to determine the appropriate assessment areas. Comparisons of biological parameters between areas have so far been inconclusive.

## INTRODUCTION

Total Irish landings of cod, whiting, sole and plaice in ICES Divisions VIIb,c and VIIj,k in 1996 were valued at IR£8.6 million (Table 1). Figure 1 shows the locations of the ICES Divisions around the Irish coast. Landings of these stocks accounted for $37 \%$ of the total value of Irish landings of these species and $17 \%$ of the overall value of Irish landings of all demersal species in 1996. Clearly, they are an important part of the Irish fishing resource yet, until 1993, were not subject to routine fisheries monitoring. Hence prior to 1993 little was known about the state of these stocks. As a result, they are subject to total allowable catches (TACs) which are based on average reported catches in preceding years (Table 2). Such TACs are agreed by the EU Council of Ministers (on the basis of proposals by the European Commission) when no analytical assessment is available and may not be appropriate to the current state of a stock.

In 1993, Ireland initiated a stock monitoring programme in VIIb,c and VIIj, k with the aim of providing an adequate time series of biological data for a full analytical assessment. At least five years of age-composition data are required to carry out a virtual population analysis (VPA)-based analytical assessment. In the meantime, it is important to make some attempt to assess the state of these stocks using the available data, so that advice can be given on the appropriate current rate of exploitation. In addition, it is important to compare biological characteristics between ICES Divisions to examine the appropriate assessment areas. This paper presents the preliminary findings of these investigations for the years 1993-1996.

There is little published work available on cod, whiting, sole and plaice in this area. An early reference to gadoid and flatfish stocks in the area was that of Andrews (1865). There was controversy in the mid-1800s surrounding the use of trawling gears in Galway Bay. Large numbers of young cod, haddock and sole were reported to be taken by trawl nets, indicating the presence of nursery grounds in Galway Bay at that time (Andrews, 1865). Ogilby (1885) reported that whiting and haddock were abundant in 1877 on the North coast, after being scarce for many years.

Surveys of the West of Ireland fishing grounds and the Irish Atlantic slope were conducted by the Royal Dublin Society, (Holt, 1891; Holt and Calderwood, 1895; Holt and Byrne, 1910), but these make little reference to the species concerned in this paper. Elkin (1955) compared spawning, growth, feeding, parasitology and population structure between east and west coast stocks of whiting.

Fives (1970) reported the occurrence of cod larvae and post-larvae (during March-April), whiting larvae and post-larvae (during May-June) and sole post-larvae (during March and August) from
surveys of plankton off the West coast. More recent work includes studies of icthyplankton distribution in the Celtic Sea (Horstman and Fives, 1994) and the West coast (O’Brien and Fives, 1995) and species distribution observed during the English Celtic Sea groundfish surveys (Warnes and Jones, 1995).

Table 3 lists surveys which currently collect information on cod, whiting, sole and plaice in ICES Divisions VIIb,c and VIIj,k.

## Fishery independent data-research surveys

The first annual Irish groundfish survey off the West coast of Ireland took place in 1990 and includes ICES Divisions VIa, VIIb and VIIj. Survey data can be used to determine the geographical distribution of fish populations. To give a true picture of the distribution of the population a survey should extend beyond the known boundaries (Hilborn and Walters, 1992). As the station positions of this survey, from 1990 to 1996, are generally located in fishable grounds, it is not possible to use this data set as an indication of any changes in distribution across ICES Divisions. The positions of the sampling stations for this survey were revised in 1997. Research survey catch data can be used to estimate total biomass using the swept area method (Sparre et al., 1989). However, as the locations of the stations are clumped in fishable grounds, these data would probably give an overestimate of abundance if used in a swept-area assessment. Therefore, the swept-area method has not been applied to this data set. In the future this survey may provide an index of abundance to be used as tuning data in a full VPA-based assessment.

The south and west young fish survey covers ICES Divisions VIa, VIIb, VIIg and VIIj and commenced in 1994. This survey was primarily designed to map inshore nursery areas over a 3 year period (1995-1997). It is hoped that this survey will provide information on spawning and nursery grounds off the west coast of Ireland.

The UK Celtic Sea groundfish survey commenced in 1981, with the primary objective of investigating the distribution and biology of the Western mackerel stock (Warnes and Jones, 1995). In 1982, the objectives of the survey were expanded to include demersal species. Warnes and Jones (1995) have documented the distributions of species observed during the survey between 1984 and 1991. These UK Celtic Sea ground fish survey data could be used to estimate the biomass of the VIIj,k stocks using the swept-area method. This data set may also provide a tuning time series for a full VPA assessment of these stocks.

The ICES co-ordinated western mackerel and horse mackerel egg survey has taken place every three years since 1977. One of its aims is to determine the distribution of mackerel and other species within the survey area. However, eggs of cod, whiting, sole and plaice are rarely observed during the survey (Steve Milligan, CEFAS, personal communication).

## Tagging studies

In November-December 1996 and March-April 1997, the Marine Institute Fisheries Research Centre (MIFRC) conducted a cod tagging study in the Irish and Celtic sea (Anonymous, 1997b). One aim of the study was to examine movements of cod within these areas.

## Fishery dependent data-monitoring of catches

The Marine Institute FRC monitoring programme for stocks in VIIb, c and VIIj,k includes analysis
of landings data using the Department of the Marine and Natural Resources (DOMNR) EU logbook data and sampling of the commercial catch for length, weight and age-composition. Preliminary assessments using these data include estimates of current fishing mortality ( F ) and the fishing mortality which gives maximum yield ( $\mathrm{F}_{\max }$ ) using catch curve and yield per recruit analysis, respectively (Anonymous, 1997c). The mesh selectivity data used in the age-based Thompson and Bell yield per recruit analyses presented in this paper were derived from North Sea data (Wileman, 1988) and are given in the text table below. The mesh sizes used were 86 mm (cod), 81 mm (whiting), 69 mm (sole) and 82 mm (plaice). The minimum legal mesh size for all towed gears fishing all target species, excluding Nephrops norvegicus, in Sub-area VII is 80 mm and for all towed gears fishing for $N$. norvegicus is 70 mm (Anonymous, 1997a). Additional international material collected as part of this programme includes French catch and effort data. It would be useful to map catch per unit effort (CPUE) data for the Irish fleet to examine the spatial distribution of CPUE, but Irish effort data are not available. The French catch and effort data are available for VIIb,c and VIIj,k. However, the French effort time series in VIIb,c and VIIj,k is not considered representative of fishing activities in the area (A. Biseau, IFREMER, personal communication).

Mesh selectivity data used in the age-based Thompson and Bell yield per recruit analyses presented in this paper. Derived from Wileman (1988).

| Stock | Age 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Cod VIIb,c | 0.00 | 0.94 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Cod VIIj,k | 0.00 | 0.96 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Whiting VIIb,c | 0.08 | 0.63 | 0.85 | 0.96 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Whiting VIIj,k | 0.12 | 0.64 | 0.87 | 0.97 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Sole VIIb,c | 0.00 | 0.00 | 0.33 | 0.88 | 0.97 | 0.99 | 0.99 | 1.00 | 1.00 |
| Sole VIIj,k | 0.00 | 0.00 | 0.62 | 0.85 | 0.93 | 0.97 | 0.99 | 0.99 | 1.00 |
| Plaice VIIb,c | 0.00 | 0.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| Plaice VIIj,k | 0.00 | 0.99 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |

## MATERIALS AND METHODS

## Landings sampling methods

Sampling of landings taken from ICES Divisions VIIb,c and VIIj,k are conducted in the fishing ports of Rossaveal, Dingle, Union Hall and Killybegs. Demersal landings are sampled for length on a weekly basis in proportion to the quantity and size grades landed for each species. Sampling for age and weight is conducted on a quarterly basis and 10 individual fish are weighed, measured and aged for each length category landed during the quarter. This quarterly age length key (ALK) is then applied to the quarterly length frequency and the resulting numbers at age data are raised to total Irish landings for that quarter. The quarterly landings at age data are then summed to give the annual landings numbers at age. Table 4 gives the number of fish sampled in each ICES Division for each species.

## Von Bertalanffy growth curves

Estimates were made of the length growth coefficients from the von Bertalanffy growth equation (Ricker, 1975):

$$
L_{t}=L_{\infty}\left(1-\exp \left[-k\left(t-t_{0}\right)\right]\right)
$$

where $L_{t}$ is length at age at time $t, L_{\infty}$ is the theoretical maximum length, $t_{0}$ is the theoretical age at length zero and k is the growth coefficient. The growth coefficients, $\mathrm{L}_{\infty}, t_{0}$ and k , were estimated by fitting a growth curve to the observed mean length at age data (1996 mean lengths at age during the spawning period), which minimised the squared residuals between the observed and expected length values.

## Current exploitation rates

The estimated annual fishing mortality in $1996\left(\mathrm{~F}_{96}\right)$ for VIIb,c and VIIj,k stocks were estimated using catch curve analysis, while $\mathrm{F}_{96}$ in adjacent stocks were estimated using VPA-based methods and taken from the relevant ICES working group documents (Anonymous, 1998a,b).

## Catch curve and yield per recruit analysis

Estimates of total mortality (Z) and fishing mortality ( F ) were obtained using catch curve analysis (Ricker, 1975). The 1996 catch numbers at age data were plotted as natural logarithms against age. Assuming constant mortality between age groups, $Z$ was estimated from the linear equation:

$$
\operatorname{LnN}_{t}=\operatorname{LnN} N_{0}-Z
$$

where $\mathrm{N}_{\mathrm{t}}$ is the number of fish surviving at time t and Z is estimated from the regression line of best fit.

F was estimated from the equation:

$$
Z=F+M
$$

where M is natural mortality and was assumed to be similar to that in stocks in adjacent areas (Anonymous, 1998a,b).

The $\mathrm{F}_{\text {max }}$ was determined from fishing mortality at maximum yield on the yield per recruit curve. Yield per recruit from all year classes within a given year was calculated using the age based Thompson and Bell yield per recruit model (Ricker, 1975):

$$
\sum_{t_{c}}^{t_{x}} \frac{F}{\bar{Z}}\left(M_{t} \times N_{t} \times(1-\exp (-((S \times F)+M)))\right)
$$

where $t_{c}$ is age at first capture, $t_{x}$ is the last age of capture, $M_{t}$ is mean weight at age $t, N_{t}$ is number of recruits at age $t, S$ is the probability of capture at age $t, F$ is fishing mortality and $M$ is natural mortality. The age-based Thompson and Bell yield per recruit model was used as it includes the effects of mesh selectivity and this gives a more realistic yield per recruit curve. Furthermore, this method is the basis of the yield per recruit methods applied to predict catches and set quotas in the ICES area (Sparre et al., 1989).

Where the yield per recruit curve did not reach a maximum, as in plaice, or where the curve was flat-topped, as in sole, the optimum fishing mortality $\mathrm{F}_{0.1}$ was also calculated. $\mathrm{F}_{0.1}$ can be defined
as the fishing mortality at which the slope of the yield per recruit curve is $10 \%$ of its value near the origin. $\mathrm{F}_{0.1}$ was estimated here by calculating the rate of change in yield per recruit for successive values of F and by interpolating to yield per recruit at $\mathrm{F}_{0.1}$ (King, 1995).

## CATCH TRENDS

Tables 5-8 show the estimated annual Irish landings for each species from ICES Divisions VIIb,c (1980-1996) and VIIj,k (1987-1996) and the international landings (1987-1996) for both areas combined. The official VIIj,k and total international landings data are available for the years 1987-1996 only, as the way in which the different countries reported Sub-area landings prior to 1987 does not allow for VIIj,k landings to be reported separately from VIIg landings.

Total international landings of each of these stocks are taken mainly by Ireland, the exception being cod landings early in the time series. France and England also exploit the gadoid stocks, but take insignificant catches of the flatfish species. Landings of all species are generally higher in Divisions VIIj,k than in VIIb,c. Estimated international landings of cod in VIIb,c and VIIj,k show a decreasing trend between 1989 and 1993 with a slight increase in the period 1994-1996 (Table 5). Estimated international landings of whiting have increased steadily over the period from just 2,000 t in 1988 to just under $8,000 \mathrm{t}$ in 1995 (Table 6). Landings of both sole and plaice have remained relatively steady over the period, although both show an increase in landings up to the period 1991 (sole) and 1992 (plaice) with a decreasing trend thereafter (Tables 7 and 8).

Irish catches of cod, plaice and sole are taken mainly by otter trawl in both VIIb,c and VIIj,k. Irish catches of whiting are taken by both seine net and otter trawl in VIIb,c and in VIIj,k. Catches by other gear types such as fixed gill nets are insignificant in these areas. Irish catches in Divisions VIIc and VIIk are relatively low.

Figures 2 to 5 show the proportion of the total Irish landings of cod, whiting, sole and plaice taken in each statistical rectangle in 1996. Cod are taken mainly in near-shore areas with higher catches taken in VIa, VIIa and VIIg than in other areas. Irish catches of whiting are concentrated in ICES Divisions VIIb, VIIg and VIIj. Irish catches of sole are relatively dispersed with a larger proportion of catches being taken from VIIj (just off the Dingle Peninsula) and from VIIa (Morecambe Bay area). Catches of plaice are more evenly distributed than for sole, with a large proportion of the catches being taken from VIa, VIIa and VIIj. It is worth noting that for sole, and also to some degree for plaice, high catches are recorded just outside of VIIb (north and south). This may indicate mis-reporting of sole caught in VIIb in adjacent TAC areas. However, the extent of such mis-reporting, if it exists, is not known.

## COD

## Distribution and movements

Cod are distributed throughout area VII and in general are found from the shore line to 600 m (Wheeler, 1969). Adult cod undertake extensive feeding and spawning migrations while juveniles do not undertake such extensive migrations. Catches of cod from the Irish west coast groundfish survey 1993-1996 indicate a relatively higher abundance of cod in areas off the Northwest coast of Ireland (ICES Division VIa). The UK Celtic Sea groundfish survey conducted in ICES Divisions VIIe-j indicates that abundance varies strongly between years depending on year class
strength (Warnes and Jones, 1995). Although only low numbers of cod are recorded per haul in normal years, they are distributed mainly on the plateau inside the 200 m line and no consistent distribution pattern is evident over the time series, although abundance decreases from North to South.

In November-December 1996 and March-April 1997, MIFRC conducted a cod tagging study in the Irish and Celtic Sea (Anonymous, 1997b). One aim of the study was to examine movements of cod within these areas. A total of 1,685 cod were tagged. By November 1998, returns numbered 166, the majority from within 7 to 15 km of the area of tagging.

The abundance of larval cod observed during the international mackerel and horse mackerel egg survey in April to June in ICES Divisions VIa,b, VIIb,c and VIIj,k is very low (Horstman and Fives, 1994). Therefore, conclusions on the dispersal of cod larvae in these areas could not be made. O'Brien and Fives (1995) analysed samples of ichthyoplankton from the international mackerel and horse mackerel egg survey and report that the abundance of cod larvae was low.

## Growth

Figures 6 and 7 give the quarterly length frequency distributions of cod landed by Irish vessels into Irish ports from ICES Divisions VIIb,c and VIIj,k in 1996 and show similar patterns between ICES Divisions. Figure 8 shows the von Bertalanffy growth curves for VIIb,c and VIIj,k cod caught in April to June. Cod in VIIj,k showed a slightly higher growth rate compared to VIIb,c $\operatorname{cod}(\mathrm{k}=0.32$ and 0.26 , respectively). Figure 9 compares the annual mean weights and lengths at age of cod taken from Divisions VIIb,c with those taken from Divisions VIIj,k; 95\% confidence intervals of the VIIb,c and VIIj,k mean lengths and weights are also given. Mean lengths and weights are similar between both Divisions except at age groups 3 and 8 . However, comparison of older age groups is not meaningful, as sample sizes are small. Table 9 compares observed mean weights at age for cod in VIIb,c and VIIj,k in 1996 with catch weight at age estimated for adjacent Divisions in 1996 (Anonymous, 1998a,b). Between the ages of 2 and 5 (from the age of full recruitment), VIIg mean weights at age are higher than in either VIIb,c or VIIj,k, VIIa mean weights vary relative to both VIIb,c and VIIj,k and VIa mean weights are lower than in either VIIb,c or VIIj,k.

## Current exploitation rates

Tables 10 and 11 show the international landings numbers at age data raised using the annual Irish age length key for each year in 1993 to 1996. Table 12 compares fishing mortality in $1996\left(\mathrm{~F}_{96}\right)$ for cod in ICES Divisions VIIb,c and VIIj,k with those in adjacent ICES Divisions.
$\mathrm{F}_{96}$ for cod in Divisions VIIb,c is estimated to be 1.09 and in Divisions VIIj,k to be $1.05 . \mathrm{F}_{96}$ in ICES Divisions VIIb,c and VIIj,k is greater than that observed in either Division VIa or Division VIIa. $\mathrm{F}_{96}$ for cod in Divisions VIIb, c is similar to that observed in 1995, while the value of $\mathrm{F}_{96}$ in Divisions VIIj,k is lower than observed in 1995 (Tables 13 and 14).

## Yield per recruit

Tables 13 and 14 give the estimates of F and $\mathrm{F}_{\max }$ for cod in 1996 and 1995. $\mathrm{F}_{\text {max }}$ in 1996 was estimated to be 0.30 (VIIb,c) and 0.35 (VIIj,k), which is consistent with that estimated for 1995 (Anonymous, 1997c). Fishing mortality was far in excess of $\mathrm{F}_{\text {max }}$ for both VIIb,c and VIIj,k cod in both years.

## WHITING

## Distribution and movements

Whiting is abundant in Area VII and is a shallow water species, occurring mostly between depths of 30 and 100 m (Wheeler, 1969). Immature fish are found inshore in depths of 5-30 m. Catches of whiting observed during the Irish west coast groundfish survey 1993-1996 indicate that whiting are abundant throughout the survey area, with a relatively high abundance both west of Donegal Bay (in VIa and VIIb) and Galway Bay (VIIb). The UK Celtic Sea groundfish survey conducted in ICES Divisions VIIe-j indicates that whiting occur over the whole of ICES Divisions VIIe-j but do not extend into deeper waters (Warnes and Jones, 1995).

Tagging studies conducted off the west coast of Scotland indicated that large-scale movements of whiting do not occur, most of the movements observed being of less than 60 miles (Newton, 1986). There was evidence of a cyclic movement between the Stanton Banks and Donegal Bay and that these movements could be associated with a minor spawning migration. However, both of these fishing grounds are within ICES Division VIa and so do not concern the current discussion of the distribution of the VIIb,c and VIIj,k stocks.

The abundance of larval whiting observed during the ICES co-ordinated western mackerel and horse mackerel egg surveys is very low (Horstman and Fives, 1994). O'Brien and Fives (1995) also analysed samples of ichthyoplankton from the above survey and report that the abundance of whiting larvae in April to June in ICES Divisions VIa,b, VIIb,c and VIIj,k was low.

## Growth

Figures 10 and 11 give the quarterly length frequency distributions of whiting landed by Irish vessels into Irish ports from the ICES Divisions VIIb,c and VIIj,k in 1996. The length frequencies showed similar patterns between Divisions, although modal values were generally higher in Divisions VIIb,c. Figure 12 shows the von Bertalanffy growth curves for VIIb,c and VIIj,k whiting caught in April to June. Whiting in VIIb,c had a higher growth rate than those in VIIj,k ( $\mathrm{k}=0.83$ and 0.52 , respectively). Figure 13 compares the annual mean weights and lengths for Divisions VIIb,c with those for Divisions VIIj,k. The annual mean lengths in age groups 3 and 4 are higher in VIIj,k than in VIIb,c whiting. Comparison of mean lengths and weights in older age groups is not feasible as the sample sizes are small.

Table 15 compares observed mean weights at age for whiting in VIIb,c and VIIj,k in 1996 with catch weight at age estimated for adjacent Divisions in 1996 (Anonymous, 1998a,b). Growth of whiting in ICES Divisions VIIb,c and VIIj,k was higher than that in either ICES Divisions VIa or VIIa. These findings concur with Elkin (1955) who compared growth of commercially caught whiting between the East coast and West coast of Ireland stocks (Nov. 1952-June 1954) and found that west coast stocks weighed slightly more than east coast stocks for the equivalent length groups. Growth in whiting in VIIb,c and VIIj,k was also higher than that observed in VIIg, apart from at age 5 and older.

## Current exploitation rates

Tables 16 and 17 show the international landings numbers at age data raised using the annual Irish age length key for each year in 1993-1996. Table 12 compares fishing mortality in $1996\left(\mathrm{~F}_{96}\right)$ for whiting in ICES Divisions VIIb,c and VIIj,k with those in adjacent ICES Divisions.
$\mathrm{F}_{96}$ in VIIb,c is more similar to that in VIIa than in VIa, while $\mathrm{F}_{96}$ in VIIj, k is lower than that observed in either VIIb,c, VIa or VIIa (Table 12). $\mathrm{F}_{96}$ in VIIb,c is similar to that observed in 1995, although $\mathrm{F}_{96}$ in VIIj,k is reduced compared to that in 1995 (Tables 13 and 14). The value of $\mathrm{F}_{96}$ in Divisions VIIj,k is just 0.52 in contrast to a value of 0.72 for 1995. A possible explanation is that there are large 1993 and 1994 year classes being exploited in the fishery (Table 16).

## Yield per recruit

Tables 13 and 14 give the estimates of F and $\mathrm{F}_{\max }$ for whiting in 1996 and 1995. $\mathrm{F}_{\text {max }}$ in 1996 was 0.70 (VIIb,c) and 0.80 (VIIj,k), which were both higher than those values estimated for 1995. Fishing mortality was in excess of $\mathrm{F}_{\text {max }}$ in VIIb,c in both 1995 and 1996. While fishing mortality was in excess of $\mathrm{F}_{\max }$ in 1995, it was slightly lower than $\mathrm{F}_{\max }$ in 1996, perhaps due to the large 1993 and 1994 year classes being exploited in the fishery.

## SOLE

## Distribution and movements

Sole is distributed throughout Area VII and is common in waters from 0 to 73 m (Wheeler, 1969). Horwood (1993) reviewed the biology of sole in ICES Divisions VIIf,g and reports that sole in these ICES Divisions is relatively isolated in that spawning grounds are discreet, nursery grounds are exclusive, a large proportion of adult sole remain in this region and few sole appear to recruit into the region.

Catches of sole observed during the Irish west coast groundfish survey 1993-1996 indicate that the abundance of sole observed throughout the survey area is relatively low. Tagging studies in the Irish Sea and adjacent waters indicate that there are probably separate stocks of sole in the Irish Sea and Bristol Channel (Anonymous, 1966). Horstman and Fives (1994) report that larvae of sole were not observed during the ICES co-ordinated western mackerel egg and larval survey.

## Growth

Figures 14 and 15 give the quarterly length frequency distributions of sole landed by Irish vessels into Irish ports from ICES Divisions VIIb,c and VIIj,k in 1996. Length frequency patterns are different between the Divisions, particularly in Quarters 3 and 4, with sole in VIIb,c generally showing higher modal lengths. Figure 16 shows the von Bertalanffy growth curves for VIIb,c and VIIj,k sole. Growth rates are slightly higher in Divisions VIIj,k sole than in VIIb,c sole ( $\mathrm{k}=0.20$ and 0.28 , respectively). Figure 17 compares the annual mean weights and lengths at age of sole taken from Divisions VIIb,c with those taken from Divisions VIIj,k; 95\% confidence intervals of the VIIb,c and VIIj,k mean weights and lengths are also given. There was little difference between mean lengths and weights of sole taken from Divisions VIIb,c and VIIj,k. Table 18 compares observed mean weights at age for sole in VIIb,c and VIIj,k in 1996 with catch weight at age estimates from adjacent Divisions in 1996 (Anonymous, 1998a, 1998b). From age 4 and older (fully recruited fish), both VIIb,c and VIIj,k observed mean weights at age were higher than those estimated for VIIa sole. However, the VIIa mean weight at age data have been obtained by smoothing the international weights at age using a quadratic fit representing July 1 values. Therefore, comparison between VIIb,c,j,k and VIIa sole mean weights at age is meaningless. Nevertheless, it is well documented that sole in the Irish sea (Division VIIa) are slower growing than stocks in adjacent areas (Anonymous, 1966). Mean weights at age of sole in VIIg were higher than that observed in

VIIb,c and VIIj,k sole.

## Current exploitation rates

Tables 19 and 20 show the international landings numbers at age data raised using the annual Irish age length key for each year in 1993 to 1996. Table 12 compares fishing mortality in $1996\left(\mathrm{~F}_{96}\right)$ for sole in ICES Divisions VIIb,c and VIIj,k with those in adjacent ICES Divisions.
$\mathrm{F}_{96}$ in sole in VIIb,c was estimated to be 0.18 and in VIIj,k to be 0.42 (Table 12). $\mathrm{F}_{96}$ in VIIj,k was higher, by $110 \%$, in 1996 compared to 1995 . A possible explanation is that there were fewer cod in the 10 to 11 age groups in the catch in 1996 (Table 20). $\mathrm{F}_{96}$ for VIIj,k cod was $133 \%$ higher than that in VIIb,c and was more similar to that observed in VIIa cod. $\mathrm{F}_{96}$ for VIIj, k is higher than that observed for 1995 (Tables 13 and 14).

## Yield per recruit

Tables 13 and 14 give the estimates of F and $\mathrm{F}_{\max }$ for sole in 1996 and 1995. $\mathrm{F}_{\max }$ was estimated to be 0.45 and 0.40 in VIIb,c and VIIj,k, respectively. $\mathrm{F}_{0.1}$ in 1996 was estimated to be 0.30 (VIIb,c) and 0.27 (VIIj,k), indicating that the VIIb,c and VIIj,k stocks are under and over-exploited, respectively.

## PLAICE

## Distribution and movements

Plaice is a shallow water species found from the shore line to 120 m depth throughout Sub-area VII (Wheeler, 1969). Young plaice ( $0-3+$ ) are found in very shallow waters from 0 to 3 m depth. Catches of plaice observed during the Irish west coast groundfish survey 1993-1996 indicate that plaice is consistently abundant in inshore areas of VIa and across into ICES Division VIIb.

The abundance of larval plaice observed during the ICES co-ordinated western mackerel and horse mackerel egg surveys is very low (Horstman and Fives, 1994). Similarly, O'Brien and Fives (1995) analysed samples of ichthyoplankton from the above survey and report that the abundance of plaice larvae in April to June in ICES Divisions VIa,b, VIIb,c and VIIj,k is low.

## Growth

Figures 18 and 19 give the quarterly length frequency distributions of plaice landed by Irish vessels into Irish ports from ICES Divisions VIIb,c and VIIj,k in 1996. Generally VIIj,k plaice show higher modal values than in VIIb,c. However, sampling levels of VIIj,k plaice in 1996 were poor (Table 2). Figure 20 shows the von Bertalanffy growth curves for VIIb,c and VIIj,k plaice. Growth coefficients are poorly estimated, however, because of high variation within older age groups. This is apparent in Figure 21, which shows very large confidence intervals in the older age groups. Mean weights and lengths at age were higher in the VIIj,k group than in the VIIb,c group. Table 21 compares the annual observed mean weights at age for plaice in VIIb,c and VIIj,k in 1996 with catch weight at age data estimates from adjacent Divisions in 1996 (Anonymous, 1998a,b). The VIIa mean weight at age data have been obtained by smoothing the international weights at age using a quadratic fit representing July 1 values. Growth rates of VIIb,c plaice (from age 4 and older) were lower than in either VIIa or VIIg. In contrast, in age groups 2-6 mean weights of VIIj,k plaice are higher than in VIIa or VIIg.

## Current exploitation rates

Tables 22 and 23 show the international landings numbers at age data raised using the annual Irish age length key for each year in 1993-1996. Table 12 compares fishing mortality in $1996\left(\mathrm{~F}_{96}\right)$ for plaice in ICES Divisions VIIb,c and VIIj,k with those in adjacent ICES Divisions.
$\mathrm{F}_{96}$ in plaice in VIIb,c was 0.34 and in $\mathrm{VIIj}, \mathrm{k} 0.54$ (Table 12). $\mathrm{F}_{96}$ in $\mathrm{VIIb}, \mathrm{c}$ and $\mathrm{VIIj}, \mathrm{k}$ was similar to that observed in 1995 (Tables 13 and 14). $\mathrm{F}_{96}$ in VIIb,c plaice was more similar to that in VIIa than in VIIj,k.

## Yield per recruit

Tables 13 and 14 give the estimates of F and $\mathrm{F}_{\text {max }}$ for plaice in 1996 and 1995. $\mathrm{F}_{\text {max }}$ in 1996 could not be estimated for plaice in VIIb,c as the yield per recruit curve did not reach a maximum. $\mathrm{F}_{\text {max }}$ for $\mathrm{VIIj}, \mathrm{k}$ plaice was 0.35 , which indicates that plaice in VIIj,k are over-exploited. $\mathrm{F}_{0.1}$ in 1996 was estimated to be 0.30 and 0.25 in VIIb,c and VIIj,k, respectively, also indicating that plaice in both areas are over-exploited.

## DISCUSSION AND CONCLUSIONS

## Biology of stocks

Prior to conducting a full assessment of the state of a given fish population, it is important to gather together all of the available information on the biology of these stocks in order to determine the distribution, population parameters and hence the geographical boundaries of these stocks. For stock assessment and management purposes it is assumed that the stock being assessed is a homogenous group of animals. That assumption means that the population has known boundaries of distribution, is not part of some larger homogenous stock and can be defined using the same population parameters for all animals in the population. An initial step in any stock assessment is to define the stock under investigation.

To date this has not been carried out for stocks of cod, whiting, plaice or sole in the ICES Divisions VIIb,c or VIIj,k. It is not known if the above stocks are separate and definable or if they are in fact part of other ICES-assessed stocks, e.g. VIa or VIIg. Ideally stock discrimination can best be achieved through genetic investigations. Previous ICES study groups have reviewed genetic methods of stock identification for fish and shellfish (Anonymous, 1993). However, there is no information on genetic discrimination of marine stocks of fish off the west and southwest coasts of Ireland. Therefore, the VIIb,c and VIIj,k stocks may be defined only by a description of the spatial distribution of commercial CPUE, from research survey abundance data, by a description of movements using tagging studies on both adults and juveniles and surveys of egg and larval dispersal and finally by comparison of population parameters between these and adjacent stocks using growth, recruitment and age structure information.

The Irish CPUE data are not available at present and French CPUE data are not considered representative of fishing activity in the area. The research survey data, from various sources, reviewed in this paper provide little basis for a decision on the identity of stocks of cod, whiting, plaice and sole in the ICES Divisions VIIb,c and VIIj,k. The Irish research survey, until 1997, did not cover the west and southwest area sufficiently to identify stock distributions. Catches from the UK ground fish survey are very low and cover only Divisions VIIg and VIIj,k. The mackerel and horse
mackerel egg surveys rarely observed larval cod, whiting, plaice or sole so information on stock distributions cannot be obtained from this source. Until recently, no tagging studies were carried out in these ICES Divisions and relatively few in adjacent areas. However, it is hoped that the recent Irish cod tagging programmes will yield information on cod distributions around the Irish coast.

Comparison of growth and fishing mortality between ICES Divisions in 1996 had yielded different findings from comparisons of the 1995 data (Anonymous, 1997c). $\mathrm{F}_{95}$ in cod in VIIb, c was similar to that in VIIa and VIIf,g,h. However, $\mathrm{F}_{96}$ in VIIb,c is higher by $78 \%$ than that in VIIa. Similar changes in $\mathrm{F}_{96}$ between ICES Divisions are apparent in other stocks, for example sole in Divisions VIIb,c and VIIj,k had a lower exploitation rate in 1995 compared to VIIa, while $\mathrm{F}_{96}$ in VIIj,k sole is similar to that in VIIa. Comparison of growth between Divisions VIIb,c and VIIj, k stock indicates that growth is similar between cod, sole and plaice, while growth in whiting is higher in VIIj,k than that in VIIb,c. A more detailed analysis over time of the changes in growth and exploitation rate is required before any conclusions can be drawn using growth and exploitation rate data.

Once the issue of stock identity has been addressed, it may be possible to determine the appropriate assessment areas for the VIIb,c and VIIj,k stocks. The 1995 ICES Southern Shelf Working Group considered the assessment areas of stocks of cod, whiting, hake, sole, plaice and anglerfish in the Irish Sea, Celtic Sea and English Channel on the basis of the available biological information on these stocks (Anonymous, 1996). That working group concluded that there was insufficient information to allow the group to redefine the assessment areas of the above stocks and suggested that further biological work is required before a decision can be made.

In conclusion any decision on the inclusion of cod, whiting, sole and plaice in assessments of adjacent areas until further information is available may be premature. Further information is required before a reliable decision can be made. Further work, which could enable a more reliable decision to be made could include analysis of the west coast ground fish survey data which includes all areas in ICES Divisions VIa, VIIb and VIIj (data from 1997 onwards), analysis of the Irish south and west coast young fish survey to identify nursery and spawning grounds, further tagging studies in ICES Divisions VIa, VIIb and VIIj and continuation of current monitoring and description of population parameters.

Nevertheless, the current management areas for the gadoid stocks include VIIb,c and VIIj,k in a larger Sub-area VII (excluding VIIa) TAC and for this reason the 1997 ICES Southern Shelf Working Group included the cod and whiting VIIj,k data in the VIIg (Celtic sea) assessments.

## State of stocks

This paper presents estimates of $\mathrm{F}, \mathrm{F}_{\max }$ and $\mathrm{F}_{0.1}$ in 1995 and 1996. The results of these analyses are consistent between years with two exceptions. Analysis of 1995 data estimated that for VIIj,k sole, $\mathrm{F}_{95}$ was below $\mathrm{F}_{\max }$ by $33 \%$. However, analysis of the 1996 catch data indicates that $\mathrm{F}_{96}$ for VIIj, k sole is above $\mathrm{F}_{\text {max }}$ and $\mathrm{F}_{0.1} . \mathrm{F}_{96}$ for whiting in VIIj, k is lower than $\mathrm{F}_{\max }$ by $35 \%$ while analysis of the 1995 catch data estimated that $\mathrm{F}_{95}$ was in excess of $\mathrm{F}_{\text {max }}$. This may be explained by the large 1993 year class which is currently being exploited in this fishery as well as a relatively large 1994 year class.

The yield per recruit analyses presented in this paper indicates that the following stocks are over-exploited: cod in Divisions VIIb,c and VIIj,k, whiting in VIIb,c, sole in VIIj,k and plaice in VIIb,c and VIIj,k. In contrast, the following stocks show values of $\mathrm{F}_{96}$ below $\mathrm{F}_{\text {max }}$ and/or $\mathrm{F}_{0.1}$ in 1996: sole in VIIb,c and whiting in VIIj,k. Whiting recruitment can fluctuate considerably between years (Anonymous, 1997c) and it is important to note that this stock indicated over-exploitation in 1995. The only stock which can reliably be described as under-exploited from this analysis is sole in VIIb,c.

While this assessment indicates that sole in VIIb,c is under-exploited in terms of the yield per recruit curve, it must be pointed out that the curve is flat-topped, as is generally the case with this species. Therefore, caution must be exercised when drawing any management inference from the relative magnitudes of F and $\mathrm{F}_{\text {max }}$. The more conservative point of $\mathrm{F}_{0.1}(0.3)$ is still higher than the current level of F . On that criterion, it is clear that the stock is under-exploited and indicates some capacity to yield increased catch weights in return for a moderate increase in fishing effort.

## Fisheries management aspects

These stocks are subjected to TACs based on average reported catches in previous years (see Table 2). These TAC levels may be inappropriate to the current state of these stocks. MIFRC monitoring of these stocks indicates that all but sole in Divisions VIIb,c are over-exploited and it is clear that the current precautionary TACs are inappropriate and will only lead to further over-exploitation of these stocks. Future work should focus on efforts to describe the biology of these stocks and to quantify sustainable exploitation levels by conducting full analytical assessments.

## ACKNOWLEDGEMENTS

The authors wish to thank Brian Casburn, John Holland, Richie Browne and Paddy O'Mahony for assistance throughout the MIFRC monitoring programme. Many thanks are also due to the workers in the auction halls and fish processors who assisted with sampling with much good will. Finally, thanks to DOMNR personnel for both supplying and for giving advice on the preparation of logbook landings data.
